Argentina Covid Report

Chris Andino

October 14 2020

Data as of 10:40 am 26-OCT-2020

New Cases

The following graphs show the overall epidemiological curves in the localities based on simple "new cases per day" as reported. Note that date of case report DOES NOT equal date of first symptoms or diagnosis, necessarily. Rather, this data is the change in cases from the previous day's report:

Log graphs

The following graphs are generated by:

$$x = Number\ of\ Days\ since\ March\ 3$$

$$y = log(Number\ of\ New\ Cases\ this\ day)$$

The regression line is drawn using the R "lm()" function over the x values.

R0 is estimated from the slope of the regression line:

$$y = a + bx$$

$$dt = log(2)/b$$

R0 over time (daily cases estimate)

These graphs rely heavily on the Epitrix, EpiEstim, and incidence modules in R. These graphs are rough estimates based on the number of new cases reported each day and not/not the actual date of registry/onset of symptoms, which provide a more-accurate picture of the rate of transmission.

The following data on serial incidence are drawn from a meta analysis of COVID-19: https://doi.org/10.1002/jmv.26041

$$\mu = 5.08\ days$$

$$\sigma = .18$$

A gamma distribution is created programatically, and the estimate_R function is run against incidence objects containing the new cases reported each day.

Better R Estimate

This data is drawn from over 1 million epidemiological records, indexed by the date the case was registered with the Ministry of Health. Cases are often registered prior to a confirmed diagnosis; therefore, this data "lags".

An incidence object is created using all confirmed cases in Argentina. The estimate_R() function from the EpiEstim package is used with the serial interval as described in the R estimate section above. While the estimate_R() function uses a rolling 7-day window, we also force the estimate away from the last five days of data due to the confirmation lag.
